Abstract: A survey of tree crown defoliation and leaf physiological traits (chlorophyll a fluorescence, nitrogen content, and stable carbon isotope composition) was carried out in the thermophilous deciduous forests in Tuscany (central Italy). In contrast to large scale surveys, where variation in defoliation can be associated with the change in environmental conditions, in a limited homogenous area the defoliation of co-existing tree species may have different significance and depends on the interaction between the characteristics of each individual species with biotic stress and environmental conditions. The survey included measurements of structural and vegetational characteristics of the forest stands, such as Leaf Area Index (LAI), basal area and tree diversity, which is expressed as the Shannon diversity index. The five tree species studied (Castanea sativa, Quercus cerris, Quercus ilex, Quercus petraea and Ostrya carpinifolia) showed species-specific crown conditions and physiological features relative to stand structure and diversity. The shape of the crowns and their area (LAI) affected forest defoliation. Tree diversity reduced defoliation in C. sativa, which was the tree species most affected by defoliation, and likewise for Q.ilex. Chlorophyll a fluorescence parameters showed lower photosynthetic efficiency in defoliated C. sativa, O. carpinifolia and Q. petraea trees. Similarly, foliar nitrogen content decreased in defoliated C. sativa and O. carpinifolia trees, whereas δ13C was higher in defoliated C. sativa. These responses may be related to the health status of C. sativa, since it was subjected to pathogen damages and insect attacks. In contrast, the mast year in O. carpinifolia may have diverted the nutrient resources from leaves to fruits, and consequently explaining the physiological effects on the tree crown. These results suggest that the combined analysis of defoliation with foliar features and stand characteristics can provide insights into tree health and vitality.

Physiological significance of forest tree defoliation: results from a survey in a mixed forest in Tuscany (central Italy)

Highlights

- Crown condition and leaf physiological traits were assessed in mixed forests
- Tree species and Leaf Area Index were the most important predictors of defoliation
- Tree diversity reduced the defoliation in chestnut and in holm oak
- Defoliation has different physiological significance in forest tree species
- Crown assessment is more informative when defoliation and leaf traits are combined

Summary

A survey of tree crown defoliation and leaf physiological traits (chlorophyll *a* fluorescence, nitrogen content, and stable carbon isotope composition) was carried out in the thermophilous deciduous forests in Tuscany (central Italy). In contrast to large scale surveys, where variation in defoliation can be associated with the change in environmental conditions, in a limited homogenous area the defoliation of co-existing tree species may have different significance and depends on the interaction between the characteristics of each individual species with biotic stress and environmental conditions. The survey included measurements of structural and vegetational characteristics of the forest stands, such as Leaf Area Index (LAI), basal area and tree diversity, which is expressed as the Shannon diversity index. The five tree species studied (*Castanea sativa, Quercus cerris, Quercus ilex, Quercus petraea* and *Ostrya carpinifolia*) showed species-specific crown conditions and physiological features relative to stand structure and diversity. The shape of the crowns and their area (LAI) affected forest defoliation. Tree diversity reduced defoliation in *C. sativa*, which was the tree species most affected by defoliation, and likewise for *Q.ilex*. Chlorophyll *a* fluorescence parameters showed lower photosynthetic efficiency in defoliated *C. sativa*, *O. carpinifolia* and *Q. petraea* trees. Similarly, foliar nitrogen content decreased in defoliated *C. sativa* and *O. carpinifolia* trees, whereas $\delta^{13}C$ was higher in defoliated *C. sativa*. These responses may be related to the health status of *C. sativa*, since it was subjected to pathogen damages and insect attacks. In contrast, the mast year in *O. carpinifolia* may have diverted the nutrient resources from leaves to fruits, and consequently explaining the physiological effects on the tree crown. These results suggest that the combined analysis of defoliation with foliar features and stand characteristics can provide insights into tree health and vitality.

Keywords: crown condition, defoliation, foliar analysis, FunDivEUROPE, mixed forests, tree diversity

Abbreviations List:

BA = Basal Area (m^2 ha^{-1});

CC = crown compression;

ChlF = Chlorophyll *a* fluorescence;

C/N = Carbon/ Nitrogen ratio;

F_0: minimum (basal) fluorescence in dark adapted samples;

F_M: maximal fluorescence in dark adapted samples;

F_V: total variable fluorescence (F_M-F_0);

$F_V/F_M = \varphi_{P0} = TR_0/ABS = [F_M-F_0]/F_M$: maximum quantum yield of PSII photochemistry of a dark adapted sample;

LAI = Leaf Area Index (m^2 m^{-2});

LI = Light Interception Index;

M_0: initial normalized slope of the fluorescence transient;

OJIP: labels of the different time-steps of the fluorescence transient;

PI_{ABS}: Performance Index on absorption basis. Index for energy conservation of photons absorbed by PSII, through the electron transport chain to the reduction of the electron acceptors in the intersystem between PSII and PSI;

PI_{TOT}: Performance Index total. Potential capacity for energy conservation until the reduction of the final acceptors beyond the PSI;

PSI: photosystem I;

PSII: photosystem II;

V_I: relative variable fluorescence at I step (30 ms);

V_J: relative variable fluorescence at the J step (2 ms);

$\delta^{13}C$: carbon isotope composition (‰);

$\Delta V_{I-P} = 1 - V_I$ = I-P phase: relative contribution of the I-P phase to the fluorescence transient OJIP (it is regarded as a measure for the efficiency of the electron flux through PSI to reduce the final acceptors of the electron transport chain);

$\Psi_{Eo} = 1 - V_J$ = Jstep = ET_0/TR_0: probability of an electron to move from reduced Q_A, the secondary PSII electron acceptor, into the electron transport chain.

1. Introduction

Tree crown defoliation is the main parameter adopted in surveys (International Co-operative Programme on Assessment and Monitoring of Air Pollution Effects on Forests, ICP Forests programme, www.icp-forests.net) to assess the health of European forests (Eichhorn et al., 2010). Defoliation is a raw visual indicator of the relative amount of foliage on the tree crown compared to a reference standard tree, and is assessed visually by trained field teams (Ferretti et al., 1999). Defoliation is an unspecific parameter integrating intrinsic tree genetic variability, site effects (soil fertility, climatic features, structure and composition of a forest stand), and external factors such as abiotic and biotic stresses. Consequently, defoliation (as assessed according to the ICP Forests criteria) is not necessarily equivalent to damage and can be considered indicative of the plastic equilibrium of a tree in a given environment.

Crown defoliation has been assessed extensively in many European countries since the 1980s, and the trends recorded are assumed to correlate with the effects of environmental stress, such as air pollution and climate change (Van Leeuwen et al., 2000; Meining and Fischer, 2011; Bussotti et al., 2014, 2015). Recent papers examining these historical trends found relationships between the increasing defoliation levels and the change of climatic conditions, with special reference to drought and heat waves (Seidling, 2007; Carnicer et al., 2011; De la Cruz et al., 2014). To increase the effectiveness of the surveys, and to evaluate the overall conditions of the trees, visual assessment of defoliation and crown status could be combined with the analysis of the functional traits most likely linked to the responses of trees to environmental stress (Bussotti and Pollastrini, 2015).

The physiological consequences of defoliation have not been thoroughly explored. Defoliation implies reduction of the leaf area, light absorbing area and the whole tree photosynthetic apparatus, and is commonly assumed that defoliated trees have reduced growth. This assumption, though supported by observational evidence (Augustatis and Bytnerowicz, 2008), does not take into account the so-called *compensatory photosynthesis*, i.e. the capacity to compensate the

120 loss of leaves with higher photosynthetic rates in the remaining foliage (Nowak and Caldwell, 1984;
121 Desotgiu et al., 2012a). Eyles et al. (2011) observed compensatory photosynthesis in aphid-
122 defoliated *Pinus radiata* D.Don, and attributed this effect to the enhanced exploitation of sunlight
123 by leaves in the inner layers of the crown. It is likely that there is a threshold of defoliation whereby
124 the remaining foliage is no longer able to restore the full photosynthetic activity. The altered light
125 regime within a thinned crown affects photosynthetic function (Lavigne et al., 2001; Turnbull et al.,
126 2007) and leaf nitrogen content that is directly related to the protein composition of the
127 photosynthetic apparatus (Ellsworth and Reich, 1995; Wright et al., 2004). Moreover, foliar
128 transpiration can be either enhanced or suppressed by the altered microclimate inside the canopy
129 (Quentin et al., 2011). It is reasonable to assume that the altered physiological functions in
130 defoliated trees may be reflected by an array of leaf features detectable with foliar analysis (Bussotti
131 and Pollastrini, 2015).

132 Among stand features, tree species composition and diversity are thought to be important.
133 Mixed forests are assumed to be more productive (Jucker et al., 2014) and more resilient to
134 environmental stress (Grossiord et al., 2014a, b) than monospecific ones that result from positive
135 interactions among tree species and the ability to exploit resources more efficiently (Bengtsson et
136 al., 2000; Balvanera et al., 2006; Knoke et al., 2008). Eichhorn et al. (2005) identified tree diversity
137 as a relevant factor that positively influences the crown conditions (i.e. reduced defoliation) at the
138 stand level in mixed oak – beech forests in Germany.

139 The present research was part of a project on the functional significance of forest
140 biodiversity in Europe (FunDivEUROPE, Baeten et al., 2013), and was carried out in mixed
141 broadleaved forests in central Italy (Tuscany). Defoliation and crown conditions, assessed
142 according to the guidelines of the ICP Forests manual (Eichhorn et al., 2010), were studied in the
143 context of stand characteristics and foliar features. Stand characteristics provide information on the
144 possible detrimental (or beneficial) effects of forest structure and composition (basal area, leaf area
145 index, tree species mixture) on crown condition. Foliar features are relevant to investigation of the

cause and/or consequences of defoliation on tree health and relative physiological functions. In contrast to large scale surveys, where variation in defoliation can be associated with the change in environmental conditions, for example drought or elevation gradients (Michel and Seidling, 2014) in a local homogenous area, with uniform climatic and soil conditions, defoliation may have contrasting significance to different tree species and depends on the interaction between the characteristics of each individual species with biotic stress and environmental conditions.

Within the hypothesis that defoliation may have different ecological and physiological meanings in tree species sharing the same environment, the present survey is aimed at exploring the effectiveness of comprehensive foliar analysis, combined with the structure and composition of the forest stands, to analyze species-specific responses connected to defoliation.

2. Materials and Methods

2.1.Site description

This study was carried out in the Italian forests (Tuscany, Colline Metallifere) of the exploratory platform of the FunDivEUROPE project (www.fundiveurope.eu, Baeten et al., 2013). The study design of the survey in Tuscany has been described by Bussotti et al. (2012). The sites were located at 43.27° N, 11.26° E, mainly at 350-450 m asl (for detailed characteristics of the plots see Table S1). The mean annual precipitation in the plots is 733 ± 42 mm and the mean annual temperature is 13.35 ± 0.38 °C (data from WorldClim-Global Climate Data, www.worldclim.org, with spatial resolution of 1x1 km). The bedrock is predominantly siliceous (sandstones and various conglomerates) and the soil is Cambisol (FAO classification), with a mean soil depth of 68 cm. Almost all of the plots have northern exposure and mean slope <50%. Thirty-six plots (30x30 m) with five focal tree species (*Quercus ilex* L.; *Quercus cerris* L.; *Quercus petraea* (Matt.) Liebl.; *Ostrya carpinifolia* Scop.; and *Castanea sativa* Mill.) were selected. Forest stands are around 50 -70 years old and originate from old coppices (the cutting of the stumps was suspended after the World War II). The trees of *C. sativa* are 60 year-old-stumps sprouted from the oldest trees cultivated in

the past for fruits and then abandoned. At present, the forests considered in this study are public and managed as natural reserves.

In this survey thirty-two plots were used (four plots were discarded because data were biased by uncontrolled conditions). The plots had different levels of tree species diversity, ranging from monocultures to a maximum of four species. The level of tree diversity was calculated as the Shannon diversity index (Staddon et al., 1997; Spellerberg and Fedor, 2003), taking into account tree basal area, for each plot.

2.2.Leaf Area Index and Light Interception Index

Canopy closure of the forest stands was assessed by means of Leaf Area Index (total one-side area of leaf tissue per unit ground surface area, m^2m^{-2}, Watson, 1947). Five measurements of Leaf Area Index (LAI) in each plot were carried out at two time points, either early in the morning (shortly before sunrise) or late in the evening (shortly after sunset) in order to work in the presence of diffuse solar radiation and thus reduce the effect of scattered blue light in the canopy. LAI measurements were carried out in early September 2012, before the beginning of leaf shedding, using a Plant Canopy Analyzer LAI-2000 (LI-Cor Inc., Nebraska). With the LAI-2000, the incident light above the canopy and the light transmission below the canopy were measured using one sensor with five fisheye light sensors (lenses), with central zenith angle of 7°, 23°, 38°, 53° and 68° (LAI-2000 manual, Li-Cor 1991). The protocol used in each plot consisted of five measurements within the plots (light transmission below the canopy), and five measurements outside the forest (as proxy of the light incidence above the canopy), in an open space that was in close proximity of the sampled plots. LAI data were processed using Li-Cor's FV2200 software (LI-COR Biogeosciences, Inc. 2010). The light transmittance measurements of the fifth ring were removed to minimize the boundary effects on LAI. The LAI value per plot was the mean value of the five measurements for each plot.

197 Furthermore, the capacity of trees to intercept light was determined. The light interception
198 index (LI, King et al., 2005) was calculated for each tree, according to Jucker et al. (2015):

199 $$LI = CPA \times CI^2$$

200 where CPA is the crown projected area of each tree (in m^2, calculated using the crown radius
201 measurements taken in the field), and CI is the crown illumination index, which scores each tree on
202 a scale of 1 to 5 based on exposure to direct sunlight (Clark and Clark, 1992).
203
204 *2.3.Crown condition assessment*
205 In each plot, between six and 12 dominant trees were selected. Six trees were selected in
206 monocultures, and three trees per focal species in mixture plots. The trees were randomly selected
207 among the trees with the largest diameter breast height. Defoliation and damage symptoms on
208 leaves and branches were assessed for each selected tree, on the visible portion of the crown, in
209 June 2012 following the guidelines of the ICP Forests (Eichhorn et al., 2010). Defoliation was
210 evaluated according to a proportion scale in 5% intervals (0= not defoliated tree; 5; 10; 15 ...
211 100%= dead tree), by comparing the sampled tree with a photographic standard ("photoguide"
212 method, Müller and Stierlin, 1990; Ferretti, 1994). Defoliation was defined as leaf loss (fallen and
213 undeveloped leaves, dieback of parts of the crown, as well the loss of foliar surface as a
214 consequence, e.g. of herbivores and/or by hail) compared to a reference tree, regardless of the cause
215 of foliage loss. Damage on leaves and branches due to biotic and abiotic factors were evaluated
216 from the ground, with binoculars, in the visible part of the crown, according to a scale with 5%
217 intervals from 0 to 100%. Causes of the damage symptoms (meteorological, mechanical, leaf
218 senescence, biotic attacks, etc.) were determined when visually recognizable. The interaction with
219 the neighbouring trees ("crown compression") was also assessed on an ordinal scale (0= crown
220 completely free in all four sides; 1= one side of the crown compressed by neighbouring trees; 2=
221 two sides of the crown compressed; 3= three sides of the crown compressed; and 4= all four sides
222 of the crown compressed).

223 *2.4.Leaf sampling*

224 From each selected tree, branches with leaves attached were sampled in two parts of the crown, the
225 highest, southern exposed part, and the lower third of the same side. The sampling was done in June
226 2012, with the assistance of tree climbers and extension loppers. Fully developed current-year
227 leaves were collected both from deciduous and evergreen species.

228

229 *2.5.Chlorophyll a fluorescence analysis*

230 Measurements of chlorophyll *a* fluorescence (ChlF) were done, after four to five hours of dark
231 adaptation of the sample, on 16 leaves for each tree. The dark adaptation of leaves was carried out
232 in hermetic black plastic bags immediately after sampling, and stored in a dark room at ambient
233 temperature. Leaves were humidified to avoid de-hydration. A long dark adaptation period was
234 necessary to reduce both dynamic and chronic leaf photoinhibition (Werner et al., 2002; Desotgiu et
235 al., 2012b; 2013) and allow leaves to return to standard conditions. Measurements were done with a
236 HandyPEA fluorimeter (Hansatech Instruments Ltd., Petney, Norfolk, UK). Plotted on a
237 logarithmic time scale, the fluorescence induction transient shows polyphasic behaviour. The
238 different time-steps of this polyphasic transient are labelled as: O (20-50 μs), J (2 ms), I (30 ms) and
239 P (peak). The latter indicates the highest fluorescence intensity (F_M), when saturating light is used.
240 Generally, F_M is reached around 0.8 s. For reviews of the theoretical background of ChlF
241 parameters obtained from the ChlF induction curve (fast kinetics) of dark-adapted leaves, see
242 Strasser et al. (2000, 2004, 2010) and Kalaji et al. (2014). ChlF parameters used in this study,
243 calculated on the basis of JIP-test (Strasser et al., 2004), were: F_V/F_M, Ψ_{Eo}, ΔV_{I-P} and Performance
244 Indices (PI_{ABS} and PI_{TOT}) (see Abbreviation list). PI_{ABS} combines three parameters related to the
245 photosynthetic activity: (1) the density of reaction centres; (2) the quantum yield of primary
246 photochemistry; (3) and the ability to feed electrons into the electron chain between PSII and PSI.
247 PI_{TOT} considers also the efficiency by which an electron can move from the reduced intersystem
248 electron acceptors to the PSI end electron acceptors.

2.6.Chemical analyses: total foliar nitrogen and carbon content; carbon isotope composition

Twenty fully expanded leaves were sampled from each sampled tree for the analysis of carbon isotope composition ($\delta^{13}C$, ‰), total carbon (C, %) and nitrogen (N, %) contents. Foliar samples were dried at 60°C for 48 h, after which the foliar samples from the same species in the same plot were pooled together and finely grounded.

For the analysis of $\delta^{13}C$ about 1.0 mg of the dried powdered material from each sample was placed into tin capsules. The analyses were performed by the Technical Platform of Functional Ecology at the INRA Forest Ecology and Ecophysiology Unit (Champenaux, France), with an isotope ratio mass spectrometer (Delta S, Finnigan MAT, Bremen, Germany). The isotopic composition of the sample was reported in delta notation ($\delta^{13}C$) relative to Vienna Pee Dee Belemnite standard.

For the determination of the N and C content, 2.5 mg of the dried sample was used. All samples were analysed by Near Infra Red Spectroscopy (NIRS), as described by Niederberger et al. (2015). For this purpose, a subset of the samples was analysed for N and C with a flash CHN Elemental Analyser (Flash EA1112 Series, ThermoFinnigan, Milan, Italy) to calibrate the NIRS spectra. The spectra were averaged from five replicates taken with a Fourier Transform Mid- and Near Infrared combination instrument (Tensor 37, Brukeroptics, Ettlingen, Germany). Each single spectrum was a mean of 32 individual scans over the range of 12000 to 4000 cm^{-1} wave numbers with a resolution of 8 cm^{-1}. The choice of samples for calibration was done for each component separately and carried out with an automatic function in the OPUS spectroscopy software (version 6.5, Brukeroptics Ettlingen, Germany) after a first prediction with an existing model. A second subset of the samples was analysed with the same equipment to validate the calibration. Calibration was performed with cross validation with one leave-out sample. The statistical parameters r^2 (coefficient of determination), RMSECV (root mean square error of cross validation) for calibration or RMSEP (root mean square error of prediction) for validation and RPD (ratio of standard error of prediction to standard deviation) were used for the evaluation of prediction quality. Leaf N and C

content at the species level for each plot was calculated as average value of three or six trees per species sampled in the plot.

2.7.Symptoms of parasitic attacks on leaves

A number of fresh leaves were selected to assess the presence of fungi (25-60 leaves per branch; 50-100 leaves per tree) and insects symptoms (30 leaves per branch). Damage symptoms on leaves that were not visible during crown evaluations were assessed. Fungal symptoms were classified into two categories: powdery mildew and leaf spots. The percentage of leaves with the presence of either type of symptom was counted. After fungal assessment, the leaves were frozen at -18°C until the assessment of the endophagous insects. Four insect guilds were considered for all tree species: miners, gallers, rollers and tiers. As the sap-feeder species *Trioza remota* Foerster was the only one easily detectable on deciduous oak leaves (nymphs stay on the underside of the leaves), there was a fifth insect guild for *Q. cerris* and *Q. petraea*. A mite guild was also assessed for *Q. ilex*. The number of leaves with at least one of the six guilds was counted. Insect damage at the tree level was then aggregated by calculating the percentage of leaves with at least one damage present. Ectophagous insects were not included in the analysis since the loss of foliar surface was already accounted in the assessment of defoliation, according to the definition of Eichhorn et al. (2010). Data of fungi and insect damage are reported as percent of damaged leaves (separately for fungi and insects) relative to the total number of assessed leaves (including both damaged and healthy leaves).

2.8.*Data analysis*

To test the univariate correlations of defoliation with the foliar and stand structure parameters on the whole sample (i.e. all tree species considered together) and for each species individually, the Spearman rank correlation test was applied. Significant differences between tree species for each parameter were assessed with a two-sample Kolmogorov-Smirnov test (for independent samples). Linear mixed models were used to determine the importance of stand structural parameters,

301 diversity and crown properties of trees as predictors of tree defoliation. A number of alternative
302 mixed effects models of defoliation were fitted and compared using Aikake Information Criteria
303 (AIC). Models included different combinations of predictors: plot basal area (BA), Leaf Area Index
304 (LAI), Shannon diversity index, crown compression and light interception index were treated as
305 fixed effects, and tree and plot were treated as random effects in the model. We performed two sets
306 of models: (1) linear mixed models for the whole dataset (i.e. all tree species together). In this case
307 the variable 'species' was included in the models as a fixed-effect variable, and (2) linear mixed
308 models for each tree species separately to examine species-specific responses to defoliation. Before
309 running the models, the correlation between the predictor variables was checked to avoid
310 autocorrelation between them. The assumptions of normality and homogeneity of variance of
311 defoliation were checked. All analyses were implemented in R (3.1.2; R Core Team 2014). For the
312 linear mixed models, the package lmerTest (Kuznetsova et al., 2014) was used.
313
314 **3. Results**
315 The results of the survey carried out in Tuscany considered 244 trees in 32 plots (Table 1). The
316 variability of each foliar and crown trait assessed, both between trees in the same plot and between
317 the plots, is provided in Table 2. The traits estimated by visual assessment (crown defoliation,
318 damage to leaves and branches, insect and pathogen attacks) showed high variability among the
319 trees and the plots. Photosynthetic performance indices also had high coefficient of variability (CV).
320 The lowest CV values were in $Fv/F_{M,}$ C content and $\delta^{13}C$.
321 The *C. sativa* monocultures had the highest BA and the lowest LAI compared to the other
322 species, and *Q. ilex* monocultures had the highest LAI (Table 1). Crown condition features for each
323 species, as visually assessed from the ground, are reported in Table 3. *C. sativa* showed the highest
324 levels of defoliation and damage to leaves and branches, followed by *O. carpinifolia*. Oak species
325 had the lowest defoliation levels and crown damage. Defoliation was significantly correlated, in
326 many species, to the presence of dead or dying branches (*C. sativa*: $r^2 = 0.53$; *O. carpinifolia*: $r^2 =$

0.22; *Q. cerris*: r^2 = 0.21; all species: r^2 = 0.53). On *C. sativa*, crown dieback was related to past attacks by the fungus *Cryphonectria parasitica* (Murr.) Barr. and oomycete *Phytophthora cambivora* (Petri) Buisman. More recently, the new agent causing defoliation and damage to leaves was attributed to the Asian wasp *Dryocosmus kuriphilus* Yasumatsu that produces galls on buds (and subsequent desiccation of branches) and leaves. The causes of branch dieback in oaks were not easily identifiable in the field, but were most likely caused by insects, e.g. *Coroebus florentinus* (Herbst), and by the opportunistic fungus *Biscogniauxia mediterranea* (De Not.) Kunze that acts synergistically with drought. Climatic agents (drought and high summer temperatures) probably induced early senescence and loss of leaves in *O. carpinifolia*.

The effects of the stand structure and tree composition as predictors of tree defoliation were examined using of univariate correlations (Table 4) and linear mixed models (Tables 5 and 6). Species and LAI were the most important predictors for defoliation in the whole sample (Table 5), whereas specific factors were important in each individual tree species. LAI was negatively correlated with defoliation in *C. sativa*, *O. carpinifolia* and *Q. cerris*. Since LAI was positively correlated with plot BA (r^2 = 0.21), we expected to observe an inverse correlation between BA and defoliation. That was indeed observed for *O. carpinifolia*, *Q. cerris and Q.ilex*, whereas for *C. sativa*, the opposite trend was noted. Tree diversity (Shannon diversity index) showed significant negative correlation with defoliation in *C. sativa* and *Q. ilex*. Light interception index (LI) and crown compression (CC) exerted significant effects on defoliation in the whole sample and in some species, but in opposite directions: LI was negatively correlated with defoliation, and CC was positively correlated with tree defoliation (Table 4).

Physiological features were measured on detached leaves. The highest foliar concentration of N was detected in *C. sativa* and the lowest in the sclerophyllous evergreen species *Q. ilex* (Table 3). The highest $\delta^{13}C$ values were observed in *Q. petraea* and the lowest in *O. carpinifolia* (Table 3). For ChlF parameters (Table 3), Fv/F_M and Ψ_{Eo} were not significantly different among species, whereas the lowest values of $\Delta V_{I\text{-}P}$ and PI_{TOT} were observed both in *O. carpinifolia* and *Q. ilex*. The

univariate correlations between defoliation and leaf features are shown in Table 4. C/N ratio was positively correlated to defoliation in many species, and negatively in the whole sample. ChlF parameters were negatively correlated with defoliation in *C. sativa* (Fv/F_M and PI_{ABS}), *O. carpinifolia* and *Q. petraea* (Ψ_{Eo}, ΔV_{I-P}, PI_{ABS} and PI_{TOT}), but positively in *Q. ilex*. $\delta^{13}C$ was positively correlated with defoliation in the whole sample and in *C. sativa*. Insect and pathogen damage (assessed on detached leaves) were negatively correlated with defoliation in *Q. cerris* and *O. carpinifolia*, respectively. Pathogen damage was negatively correlated with defoliation in the whole sample.

4. Discussion

In the present survey, the main patterns of defoliation were associated with parasitic attacks (*C. sativa*) or abiotic agents (*O. carpinifolia*). Stand factors could enhance or suppress tree crown defoliation. The closure of the canopies, expressed with high LAI, was the main stand factor associated with reduced defoliation. The positive correlation between crown compression and defoliation in some species seemed to suggest an opposite trend, i.e. enhanced defoliation. This apparent contradiction can be explained by a negative effect of the aboveground competition between crowns, resulting in mechanical abrasions (Hajek et al., 2015). In *C. sativa*, the positive correlation between basal area and defoliation was explained by the high defoliation rates of old large chestnut trees under parasitic attacks.

Tree diversity reduced tree defoliation in *C. sativa* and *Q. ilex*. In the studied forests, *C. sativa* was severely affected by the Asian gall wasp *D. kuriphilus*, which constitutes a tremendous threat for tree health and fruit production (Quacchia et al., 2008; Panzavolta et al., 2012; Battisti et al., 2014). Tree diversity is expected to reduce the intensity of insect herbivore attacks (Jactel and Brockerhoff, 2007). Several hypotheses have been proposed to explain this associational resistance effect of diverse plant communities (Tahvanainen and Root, 1972). According to the "resource concentration hypothesis" (Root, 1973), the probability of a host plant to be located by insects

379 decreases in plurispecific systems. Non-host plants could disrupt chemical or physical cues used by
380 herbivores to locate a suitable host (Huber and Borden, 2001; Castagneyrol et al., 2013). In addition,
381 the "natural enemy hypothesis" (Root 1973; Russell 1989) suggests that richer plant assemblages
382 provide natural enemies with more complementary resources and habitats, thus promoting top-down
383 regulation of herbivores. Tree species richness *per se*, however, has no effect on the probability of
384 attack by pests. The infestation rate is also strongly dependent on plot composition (Castagneyrol et
385 al., 2014) and species-specific interactions. Guyot et al. (2015) found the decrease of *D. kuriphilus*
386 attacks on chestnut tree crowns in more diverse forests. The authors suggested that it is connected
387 with the presence of oak species, housing cynipid galls and associated parasitoids (Aebi et al., 2006,
388 2007, Panzavolta et al., 2013, Quacchia et al., 2013). At opposite, in *Q. ilex*, the negative correlation
389 between defoliation and the Shannon diversity index was probably due to the smaller size of this
390 species in comparison with the tallest deciduous oaks, and as a result, *Q. ilex,* a sciaphilous species,
391 benefits from the shading effect of dominant canopies.

392 Foliar damage assessed from the ground (ICP Forests protocol) and on detached leaves gave
393 contrasting information. Ground assessment provides a general overview and allows the
394 identification of the most relevant foliar attacks affecting the status of the whole crown. Fungal and
395 insect damages assessed directly from leaves on hand may, however, be indicative of a demography
396 in equilibrium with the crown status (Leather, 2005), although these parameters showed high
397 variability (Table 2).

398 Among the physiological traits assessed, the C/N ratio was related to defoliation in many
399 species. For each species considered individually, the C/N ratio was positively associated with
400 defoliation (reduction of N with increasing defoliation), the opposite was observed in the whole
401 sample. This apparent contradiction can be explained by the result of the combination of species-
402 specific behaviors, with the most N-rich species (*C. sativa*) being also the most defoliated. In *O.*
403 *carpinifolia*, we found increasing C/N ratio associated with decreasing levels of photosynthetic
404 efficiency in defoliated trees. Nikiforou and Manetas (2011) found that the decrease of $\Delta V_{I\text{-}P}$ may

405 be indicative of low nitrogen foliar concentrations. In *O. carpinifolia*, defoliation was probably
406 related to intense fructification and seed production (masting) that occurred during the sampling
407 period. Masting is a well know phenomenon that has a relevant role in forest ecology (Kelly and
408 Sork, 2002; Packham and Hilton, 2002), whereby the recurrence of mast year may be indicative of
409 altered environmental conditions (Jonard, 2009). In *O. carpinifolia*, this behavior was already
410 observed in previous surveys in Tuscany (Bussotti, data not published). Inverse relationships
411 between fructification and defoliation was found on *Fagus sylvatica* L. (beech) in central Europe by
412 Eichhorn et al. (2005) as a consequence of nutrient allocation strategies (carbon and nitrogen were
413 diverted from leaves to increase its availability for fructification, Jonard et al., 2009). Thomas et al.
414 (2002) demonstrated that unbalanced nutritional status (in this case decreased K/N and P/N ratios,
415 and decreased production of allochemicals caused by high nitrogen deposition) was responsible of
416 poor crown conditions in European species of deciduous oak (*Quercus robur* L. and *Q. petraea*),
417 and pathogenic attacks were favoured.

418 Defoliation in *C. sativa* was correlated to the capacity to trap the solar energy (Fv/F_M and
419 light interception index). A reduction of the photosynthetic efficiency, measured with the JIP-test,
420 was also observed by Ugolini et al. (2014) in *C. sativa* leaves attacked by *D. kuriphilus*. According
421 to the authors, the quantum yield efficiency (Fv/F_M) was not negatively affected by the presence of
422 galls, but Ψ_{Eo} was affected. Deciduous oaks had low levels of defoliation, almost always falling
423 below the value of 25%, which is the threshold that defines "healthy" trees (Eichhorn et al., 2010).
424 This narrow range of defoliation impeded the effective analysis of the relationships with ChlF
425 parameters, although contrasting patterns were detected on *Q. petraea* and *Q. ilex*. The positive
426 correlation between defoliation and ChlF parameters in *Q. ilex* can be attributed to better
427 exploitation of sunlight in lighter crowns, as explained by the enhanced electron transport (Bussotti,
428 2004).

429 Higher values of $\delta^{13}C$ (less negative values) in defoliated trees revealed a potential relation
430 between defoliation and drought stress. High $\delta^{13}C$ content in plant tissues indicates decreased leaf

431 internal CO_2 concentration that can be caused by a decrease in stomatal conductance induced, for
432 example, by drought (Francey and Farquhar, 1982). In the present research, we found a positive
433 correlation between $\delta^{13}C$ and defoliation in the whole sample, and among individual tree of *C.*
434 *sativa*. The loss of foliage mass may cause higher irradiation levels and a drier microclimate in the
435 crown, which may induce stomatal closure. As far as *C. sativa* is concerned, the relatively high
436 values of $\delta^{13}C$ may be a result of parasitic attacks on the functionality of roots (*P. cambivora*) and
437 xylem (*C. parasitica*), and by the leaf damage (*D. kuriphilus*).

438 There are many papers about the relationship between crown defoliation and drought, where
439 water shortage is a causal factor, both in space (increasing defoliation in drier sites, Zierl, 2002) and
440 in time (increasing defoliation after drier years, Solberg, 2004; Ferretti et al., 2014). In previous
441 research carried out in Italian beech forests, Bussotti et al. (2005) found that the most defoliated
442 trees, growing in the southernmost drought-prone sites, had smaller and thicker leaves, and higher
443 C/N ratio, than trees growing in mesic sites. Drought is expected to play an increasing role in
444 Mediterranean forests in light of climate change (Galiano et al. 2012; Bussotti et al., 2014, 2015).
445 The present paper supports the idea that the use of physiological indicators in forest surveys may be
446 relevant to validate the responses observed in controlled conditions and field studies realized "ad
447 hoc" over a larger scale (Iovi et al., 2009; Galiano et al., 2012; Moreno-Gutiérrez et al., 2012;
448 Granda et al., 2014).

449

450 **5. Conclusions**

451 The results presented here suggest that defoliation is not an unequivocal phenomenon, but may have
452 different causes and physiological significance in different tree species. Defoliation in *C. sativa* was
453 associated with insect and pathogen attacks, and subsequently resulted in increased exposure to
454 drought. In *O. carpinifolia*, the effect of fruiting with the diversion of N from leaves to fruit was
455 found. In these two species, defoliation was accompanied by the decrease of photosynthetic
456 efficiency, as observed by JIP-test parameters. The opposite pattern observed in *Q. ilex* (higher

457 photosynthetic efficiency in more defoliated trees) maybe related to specific physiological strategies
458 to exploit sunlight.

459 This "leaf trait analysis" approach can be applied both at local and large scale for purposes
460 of forest management and policy. Locally it can be used to individuate the most appropriate
461 structural characteristics of the forests to enhance the physiological efficiency of the different tree
462 species. Moreover, through surveys repeated over time, it would be possible to assess the responses
463 of trees to sylvicultural practices. At a large scale, this analysis can contribute to strengthening the
464 informative potential of the ongoing routine monitoring activities (e.g., ICP Forests) providing
465 insights about the ecological equilibrium of different tree species in a changing environment. In this
466 perspective the leaf traits analysis can provide basic knowledge to support the elaboration of
467 adaptive strategies.

468 The main limitation of this study relies in the difficult of representing, with a consistent
469 number of replicates (within and among forest stands), all the possible combination of tree species
470 mixture whilst avoiding bias deriving from the variability of environmental factors (e.g., bedrock
471 and exposure). Such limitations are due to the characteristics of landscape fragmentation and the
472 difficulty of sampling leave in high forests. A large scale survey with a consistent number of forest
473 stands may provide more robust data evidencing general tendencies and avoiding interference from
474 local factors. The analysis of the variability of the foliar features assessed in this study (Table 2) can
475 help to select the more robust and reliable parameters to design an effective cost-benefit surveys
476 according to the criteria of ecological monitoring (Elzinga et al., 2001).

477

478 **Acknowledgements**

479 The research leading to these results received funding from the European Union Seventh
480 Framework Programme (FP7/2007-2013) under Grant 265171. We are grateful to the Regional
481 Government of Tuscany, the National Forest Service (Corpo Forestale dello Stato) – UTB Follonica,
482 the Comunità Montana Colline Metallifere, the Municipality of Volterra for having supported the

483 logistic aspects of the research. We thank also Federico Selvi, Andrea Coppi and Elisa Carrari for
484 the survey design and technical support. Thanks to the tree climbers Cinzia Sarti, Claudio Santelli,
485 Giovanni Lotti and Francesco Ierimonti for the leaf collection. We thank Tommaso Jucker for the
486 availability of light interception index data, as well as Renate Nitschke, Jurgen Bauhus, Francoise-
487 Xavier Joly and Stephan Hattenschwiller for their contribution in the NIRS and chemical reference
488 analysis.

Highlights

- Crown condition and leaf physiological traits were assessed in mixed forests
- Tree species and Leaf Area Index were the most important predictors of defoliation
- Tree diversity reduced the defoliation in chestnut and in holm oak
- Defoliation has different physiological significance in forest tree species
- Crown assessment is more informative when defoliation and leaf traits are combined

Reviewers' Comments
Authors responses

Reviewer #1:
The authors followed the main recommendations of the first review. From my view, the value of the paper increased significantly. I recommend accepting the paper for printing after some minor changes. One point for further considerations and improvement: Some phrases and statements of the paper are not precise enough. Some examples:
Introduction gives the scientific environment of the study and questions that might be still open. However, it should be stated even more clearly what is the task of the study and what can be achieved by the scientific concept. It seems important to specify what can be achieved and what is out of reach by methodological limitations and difficulties of the study.
The limitation are discussed in Conclusions. In Introduction some statements are changed:
"The present research was part of a project on the functional significance of forest biodiversity in Europe (FunDivEUROPE, Baeten et al., 2013), and was carried out in mixed broadleaved forests in central Italy (Tuscany). Defoliation and crown conditions, assessed according to the guidelines of the ICP Forests manual (Eichhorn et al., 2010), were studied in the context of stand characteristics and foliar features. Stand characteristics provide information on the possible detrimental (or beneficial) effects of forest structure and composition (basal area, leaf area index, tree species mixture) on crown condition. Foliar features are relevant to investigation of the cause and/or consequences of defoliation on tree health and relative physiological functions. In contrast to large scale surveys, where variation in defoliation can be associated with the change in environmental conditions, for example drought or elevation gradients (Michel and Seidling, 2014) in a local homogenous area, with uniform climatic and soil conditions, defoliation may have contrasting significance to different tree species and depends on the interaction between the characteristics of each individual species with biotic stress and environmental conditions.
Within the hypothesis that defoliation may have different ecological and physiological meanings in tree species sharing the same environment, the present survey is aimed at exploring the effectiveness of comprehensive foliar analysis, combined with the structure and composition of the forest stands, to analyze species-specific responses connected to defoliation." [line 139-155]

I appreciate to combine aspects of site, stand, LAI, defoliation, C/N, Carbon isotopes and ChlF as well as insects and fungi in the given study. However, my concern is: The main questions raised are quite general. Is the paper able to give answers to general questions such as (Summary 41) "to detect the main causes of tree defoliation in forest tree species"…. E. g. water use and drought are not at all included in the concept.
The main question is the different responses of tree species sharing the same environment. In Summary the statement was changed:
"In contrast to large scale surveys, where variation in defoliation can be associated with the change in environmental conditions, in a limited homogenous area the defoliation of co-existing tree species may have different significance and depends on the interaction between the characteristics of each individual species with biotic stress and environmental conditions". [line 40-44]

Another example: the authors relate the results to forest management. However, is there a real good argumentation how to use the results for practical forestry? Under which conditions show the results a general applicability in practical forestry?
Forest management issues are not included now in Summary and Introduction. In Conclusions the statements were changed:

"This "leaf trait analysis" approach can be applied both at local and large scale for purposes of forest management and policy. Locally it can be used to individuate the most appropriate structural characteristics of the forests to enhance the physiological efficiency of the different tree species. Moreover, through surveys repeated over time, it would be possible to assess the responses of trees to sylvicultural practices. At a large scale, this analysis can contribute to strengthening the informative potential of the ongoing routine monitoring activities (e.g., ICP Forests) providing insights about the ecological equilibrium of different tree species in a changing environment. In this perspective the leaf traits analysis can provide basic knowledge to support the elaboration of adaptive strategies." [line 459-467]

Is the investigation and inclusion ChlF sufficient to state: "the present paper demonstrated the feasibility of the use of physiological indicators in forest surveys?
This statement is deleted. It is now added a discussion about the limits and difficult of the survey. [line 468-476]

Discussion tries to explain major results quite completely. However, it is not adequately stated, which contradictions might be given by restrictions of the data base or by the complexity of the concept. Questions such as: What might be a needed next step to clarify complex results. Which consequences can be derived from the experimental set up (samples, repetitions). Which limitations are given by statistical methods?
In conclusions the statements were changed:
"The main limitation of this study relies in the difficult of representing, with a consistent number of replicates (within and among forest stands), all the possible combination of tree species mixture whilst avoiding bias deriving from the variability of environmental factors (e.g., bedrock and exposure). Such limitations are due to the characteristics of landscape fragmentation and the difficulty of sampling leave in high forests. A large scale survey with a consistent number of forest stands may provide more robust data evidencing general tendencies and avoiding interference from local factors. The analysis of the variability of the foliar features assessed in this study (Table 2) can help to select the more robust and reliable parameters to design an effective cost-benefit surveys according to the criteria of ecological monitoring (Elzinga et al., 2001)." [line 468-476]

Therefore, I would prefer to be more precise what the authors really intend to explain. This is mainly valid in the chapter introduction (questions) and discussion/summary. In my opinion, this would be a further step of improvement of the overall value of the paper.

Subject:FORECO15463R2: **Submission revised manuscript**

Pollastrini M., Feducci M., Bonal D., Fotelli M., Gessler A., Grossiord C., Guyot V., Jactel H., Nguyen D., Radoglou K., Bussotti F., '**Physiological significance of forest tree defoliation: results from a survey in a mixed forest in Tuscany (central Italy)'**

Dear Editor,

We herewith enclose a new revised version of the manuscript and a detailed list of responses to each point raised by Reviewers.

We thank the two anonymous Referees for their constructive comments and suggestions, which has helped us to improve the paper.

Waiting for your kind consideration,

Yours Sincerely,

Martina Pollastrini
